Scientific Report for Loan 914:

Interaction of Tectonics and Magmatism in the Askja and Krafla Spreading Segments of Iceland

Prof. Robert S. White (rsw1@cam.ac.uk), Jon Tarasewicz, Tim Greenfield & Rob Green September 2013

Abstract

This loan comprised 40 SEIS-UK seismometers operating alongside 10 Cambridgeowned seismometers to provide coverage of 150 km of the Northern Volcanic Zone (NVZ) active spreading centre in Iceland, with denser local arrays around Askja and Krafla volcanoes, during July 2010 – September 2011 (Fig. 1). The loan of 30 SEIS-UK seismometers was extended to September 2012 to enable monitoring of increased seismic activity under Vatnajökull at the south end of the NVZ. We purchased a further 15 seismometers using NERC funding, thus maintaining a network of 55 instruments during the extension period. The work was supported by a NERC research grant and NERC post-doc and Ph.D studentships as well as several M.Sci. research projects. Preliminary results include: mapping of several thousand earthquakes along the rift zone in both the lower and upper crust; tomographic evidence for the magma chamber under Askja; detailed analysis of how strike-slip faulting accommodates shear in the transfer zone between rift segments; evidence for strongly non-double-couple source mechanisms at Krafla; demonstration of faulting in the brittle layer at extremely low stress drops of 1-3 bars, probably caused by migration of carbon dioxide from an underlying magmatic intrusion.

Background

The Northern Volcanic Zone (NVZ) of Iceland is persistently seismically active, ultimately due to spreading of ~2 cm/yr being accommodated across its rift segments. However, the permanent monitoring network of the Icelandic Meteorological Office (IMO) is relatively sparse in the NVZ. Our network has provided far denser coverage around Askja (last eruption 1961) and Krafla (last eruption episode 1975–1984) volcanoes, with additional stations along the length of the NVZ beyond and between these two most recently active volcanic centres (Fig. 1). Increased activity under Vatnajökull, at the southern end of the network, is of particular interest because several sub-glacial volcanoes there have the potential to form both hazardous *jökulhlaups* (glacial floods) and ash-rich plumes as a result of ice-magma interaction,

exemplified by Eyjafjallajökull volcano in 2010. Monitoring and understanding the magmatic plumbing systems of Askja (which erupted explosively in 1875 with catastrophic consequences for much of east Iceland) and Krafla (which has a significant commercial geothermal power plant operating in its caldera) remains very important.

FIGURE 1: Network location map for September 2011 – July 2012 during the second year of Loan 914. Sites also operated July–Sept 2011 (maximum network size) are shown by small black stars. Inset (a) shows location of main map. Top inset shows Krafla caldera. Grey-shaded zones show fissure swarms associated with volcanoes (labelled) in the NVZ. See Appendix for exact station locations.

Survey procedure

Loan 914 aggregated instruments that were already deployed in Iceland under Loans 857 (15x 16 Gb Güralp 6TDs around Askja) and 891 (15x 8 Gb 6TDs around Krafla caldera). Additional to these 30 instruments, ten more 16 Gb 6TDs were deployed in July 2010 under Loan 914. Ten Cambridge-owned 4 Gb instruments were also already in the field, giving a total network of 50 instruments in July 2010. In July 2011, we deployed 10 new Cambridge-owned 16 Gb 6TDs and five 16 Gb ESPDs (network total = 65 instruments). Subsequently, in September 2011, we returned 10 SEIS-UK 6TDs (8 Gb), whilst 30 SEIS-UK 6TDs and all Cambridge-owned instruments remained deployed under the Loan 914 extension (network total = 55 instruments). The Loan 914 period ended in September 2012. The network was serviced in July/August 2010, March (Krafla only)/July/September 2011, and April (Askja only)/July 2012, with some redistribution of stations in July/September 2011 and July 2012. Station locations are given in the Appendix and Figure 1.

Seismometers were either buried directly in soil or on cement plinths inside barrel vaults. We recorded at 100 or 200 samples per second (sps) during the shorter summer service interval, and 50 sps over winter, which allowed us to record continuously all year without exceeding the 16 Gb sensors' memory capacity. Stations were powered by a combination of solar panels (\geq 120 W for sites expected to run all winter), batteries (\geq 230 Ah, often \geq 345 Ah) and, in some cases, wind turbines. Use of wind turbines was only partly successful due to ice accumulation and very strong winds during the Icelandic winter. Nevertheless, power loss over winter was limited by the generous use of batteries and solar panels, which were mounted on wooden A-frames at least 50 cm above the surface. Equipment failure was minimised compared to previous campaigns by mounting breakout boxes on stakes above ground such that they did not become waterlogged and frozen in ice.

Data quality

The majority of local events recorded in the NVZ are of only small magnitudes ($M_L < 2$). Nonetheless, many local events have clear P- and S-wave arrivals (Fig. 2), and regional events of $M_L \ge 2$ can be observed across the entire network along the length of the NVZ.

Processing and modelling

Data were quality controlled in the field and converted to miniseed format using SEIS-UK standard procedures. An initial catalogue of automatic earthquake locations has been obtained using Coalescence Microseismic Mapping (CMM) software (Drew *et al.*, 2013). We have refined earthquake locations using manual P- and S-wave arrival picks and investigated source mechanisms using P-wave first-motion polarities and P/S amplitude ratios for simple double-couple source inversions as well as full moment tensor solutions (Green *et al.*, in press; Watson *et al.*, in prep.). Manual P- and S-wave arrival time picks have been used to carry out tomography around Askja (Mitchell *et al.*, 2013).

FIGURE 2: Data examples. (Left) Event recorded in the transform zone between Askja and Kverkfjöll rift segments, with vertical component traces and picked P-wave first-motion polarities aligned on the first arrival (from Green et al., in press). (Right) Example vertical (red) and horizontal (blue) component traces recorded on stations in Krafla caldera.

Preliminary findings

During the loan period, the network has recorded several thousand events at Krafla and Askja, including deep crustal events (Fig. 3). At Krafla, all well-constrained earthquakes are shallow (< 4 km) and coincide spatially with the location of either geothermal fields associated with the power station in the caldera, or are located above, or close to, the putative magma chamber. At Askja, most activity is also at relatively shallow levels, above the brittle-ductile transition (~6–7 km), but we also observe much deeper activity in the normally ductile mid- and lower crust which we attribute to melt movement.

FIGURE 3: Histogram of earthquakes detected in the south part of the network around Askja (yellow <10 km deep; blue >10 km deep). Black line (scale right) shows number of stations operating at the time (only for the Askja part of the network).

Interpretation to date

We interpret all of the seismicity deeper than approximately 8 km as being associated with magma migration and intrusion in the crust (Key *et al.*, 2011; White *et al.*, 2011; White *et al.*, 2012), where the high strain rates cause brittle failure in otherwise ductile crust. Shallower earthquakes are likely due to hydrothermal fluid circulation driven by heat from magma chambers, geothermal exploitation and tectonic stresses across the rift zone. Preliminary tomographic results suggest that there is a magma chamber at ~6–8 km depth beneath Askja (Fig. 4; Mitchell *et al.*, 2013). We have found evidence (in the earthquake distribution and fault-plane solutions) for spreading being accommodated by bookshelf faulting in the transfer zone between the Askja and Kverkfjöll rift segments (Fig. 5; Green *et al.*, in press). At Krafla, we observe well-constrained, strongly non-double-couple earthquakes that we interpret as being associated with the evacuation and collapse of fluid-filled cavities (Watson *et al.*, in

prep.). Stress modelling and the timing of earthquakes around a mid-crustal dyke intrusion at Upptyppingar (Fig. 4) suggest that subsequent, shallower earthquakes are triggered by volatiles that have exsolved from the magma in the mid-crustal dyke (Martens & White, 2013).

FIGURE 5: Top: Hypocentre locations and faultplane solutions for earthquakes on NNE-SSWstriking faults that accommodate shear in the transform zone between Askja and Kverkfjöll rift segments. **Right**: Cartoon illustrating shear and rotation of blocks in the transform zone between the volcanic rift segments (Green et al., in press).

Conclusions and Recommendations

The network deployed along the NVZ with a focus on Askja and Krafla volcanoes has enabled a significantly lower detection threshold than the permanent national monitoring network operated by the IMO. The dense array has facilitated detailed analysis of earthquake locations, tomography and source mechanisms, thus allowing us to image magmatic intrusions and speculate on source processes and the relationship between magmatism and the seismicity we have recorded. The rich dataset acquired under Loan 914 is the subject of ongoing study, including denser travel time tomography around Askja and Krafla, investigation of anisotropy caused by cracks in the upper crust and in the Krafla geothermal area, regional crustal velocity structure control by ambient noise analysis, receiver function analyses of Moho and mantle discontinuities, ongoing temporal changes in seismicity caused by the 2007 Upptyppingar intrusion, and the use of regional earthquakes for crustal structure studies along the NVZ.
